A PRACTICAL APPROACH FOR OPTIMIZING AIRCRAFT TRAJECTORIES IN WINDS

Hok K. Ng, University of California, Santa Cruz, Moffett Field, CA 94035
Banavar Sridhar and Shon Grabbe, NASA Ames Research Center, Moffett Field, CA 94035

Abstract

Developing optimal aircraft trajectories that minimize flight times, fuel burn, and associated environmental emissions not only enhances air traffic flow but also helps the aviation industry cope with increasing fuel costs and reduce aviation-induced climate change. This study develops a trajectory optimization algorithm for minimizing aircraft travel time and fuel burn by combining a method for computing minimum-time routes in winds on multiple horizontal planes, and an aircraft fuel burn model for generating fuel-optimal vertical profiles. It is applied to assess the potential benefits of flying user-preferred routes for commercial cargo flights operating between Anchorage, Alaska and major airports in Asia and the contiguous United States. Flying wind optimal trajectories with a fuel-optimal vertical profile reduces average fuel burn of international flights cruising at a single altitude by 1-3%. Long-haul flights not only gain fuel savings from en-route step climbs but also potentially benefit from high-speed winds at higher altitudes. The potential fuel savings of performing en-route step climbs are not significant for many shorter domestic cargo flights that have only one step climb. Wind-optimal trajectories reduce fuel burn and travel time relative to the flight plan route by up to 3% for the domestic cargo flights. However, for trans-oceanic traffic, the fuel burn savings is up to about 10%. In general, the savings are proportional to trip length, and depend on the en-route wind conditions and aircraft types.

Introduction

Advanced air traffic management systems are designed to optimize the throughput and efficiency of the national airspace system in the United States to accommodate growth in air traffic. Developing optimal aircraft trajectories not only enhances air traffic flow but also helps the aviation industry cope with increasing fuel costs and helps to reduce aviation-induced climate change. Classical aircraft trajectory optimizations are solved by applying calculus of variations to determine the optimality conditions, requiring the solution of non-linear Two-Point Boundary Value Problems (TPBVPs) [1]. In order to reduce the modeling order and hence the complexity, the energy state approximation has been successfully applied to generate an optimal vertical flight profile [2, 3]. Alternatively, a more general solution to aircraft trajectory optimization can be obtained by singular perturbation theory which approximates solutions of high order problems by the solution of a series of lower order systems with the system dynamics separated into low and fast modes [4, 5]. However, finding the global optimal solutions to the TPBVPs remains a daunting task.

With the tremendous advancement in numerical computing power, TPBVPs can be converted to nonlinear programming problems that are solvable even for problems with many variables and constraints using numerical algorithms such as direct collocation methods. Neglecting aircraft dynamics and applying shortest path algorithms in graph theory, an optimal trajectory can be approximated by the path that minimizes the total link cost connecting the origin and destination in a pre-defined network. The graph methods often require large computation time and memory space but guarantee global optimal solutions. These numerical methods are widely applied for problems in constrained airspace such as minimum cost-to-climb and obstacle-avoidance. However, the majority of the aforementioned trajectory optimizations neglect the effect of wind in the problem formulation.

The following studies include wind effects. In 1931 Ernst Zermelo first proposed the minimum-time path problem for a boat moving through a region of strong currents. Bryson and Ho approached the problem by determining the analytical equation governing the optimal heading dynamics that satisfies Pontryagin’s Minimum Principle [1]. This results in a solution to the minimum-time path for aircraft
travel at a constant altitude and speed in strong winds
given correct choice of the initial heading. Generally,
the initial heading angle can be obtained by an
iterative process but convergence problems may
occur due to the presence of nonlinearities such as jet
streams. The search could converge to a local
minimum depending on the initial choice. Recent
studies propose selecting the initial heading by
combining calculus of variations and graph theory,
and claim that these methods always generate global
optimal solutions with moderate computational effort
[6, 7]. These studies are focused on computing the
minimum-time path at a single flight level and have
not considered the minimum-fuel route that is divided
into segments at several flight levels, identified by
incorporating aircraft weight and fuel burn modeling
into the optimization procedures.

This study develops a practical trajectory
optimization algorithm for aircraft that minimizes
cost of time and fuel burn by combining the method
for computing minimum-time routes in winds on
multiple horizontal planes and the aircraft fuel burn
model for generating fuel-optimal vertical profiles. It
is applied to evaluate the potential benefits of flying
wind-optimal routes in a seamless airspace for
commercial cargo flights operating between
Anchorage, AK and major airports in Asia and the
contiguous United States.

The section on Aircraft Trajectory Optimization
describes total operating cost, and develops the
vertical profile and horizontal maneuver that
minimize fuel burn and travel time in winds for
commercial aircraft. The section on Experimental
Setup applies the optimization algorithm to calculate
wind-optimal trajectories for commercial cargo
flights between Anchorage, AK to major cities in the
U.S. and Asia. The Results section presents potential
benefits of flying minimum-time trajectories in winds
with a fuel optimal vertical profile. The Conclusions
section presents conclusions that can be drawn from
the paper.

**Aircraft Trajectory Optimization**

This section presents the optimal trajectory
algorithm that minimizes the total cost of travel time
and fuel consumption for aircraft on a spherical
surface. Optimizing performance of a single aircraft
from takeoff to landing in the presence of air traffic
constraints and winds is computationally intensive
and time consuming. Future air traffic simulation
systems will be required to optimize and simulate
tens of thousands of aircraft trajectories in seconds or
minutes. However, it is impractical and may not be
necessary for these systems to generate thousands of
optimal and detailed aircraft trajectories. The details
of the trajectory optimization required depend on the
performance index, the approach and the application.

This study adapts a practical optimization
approach by assuming a typical structure for an
aircraft trajectory and focuses on optimizing direct
operating cost during cruise when the time and fuel
savings are the most. A typical aircraft trajectory
consists of an initial climb, a steady-state cruise, and
a final descent. Here, aircraft performance is
optimized for the cruise phase only. Typical aircraft
profiles are applied for generating trajectories during
initial climb and final descent since additional air
traffic constraints are involved in these stages and
cruise time and fuel savings are generally small
compared to those during cruise. The cruise
trajectory is divided into segments on several
altitudes as the optimal cruise altitude increases due
to the reduction in aircraft weight as fuel is used. The
legal cruising altitudes and the en-route step climb
times are optimized based on Eurocontrol’s Base of
Aircraft Data Revision 3.6 model. The aircraft
optimal heading during cruise is the solution of the
Zermelo problem derived on a spherical Earth surface
in the absence of constraints. The horizontal
trajectory segments are optimized based on the cost-
to-go associated with extremals (trajectories)
generated by forward or backward integrating the
dynamical equations for optimal heading and aircraft
motion from various points in the airspace. This
computationally efficient algorithm searches for
optimal solutions by combining calculus of variations
and dynamic programming.

The next subsection defines aircraft operating
cost and outlines the optimization procedures. The
optimization procedures include two stages. The
subsection on Optimal Vertical Profile describes
solving the optimal aircraft cruise altitudes and
en-route step climb times. The subsection on Horizontal
Trajectory Generation presents the aircraft model and
the procedures for calculating optimal aircraft
headings in winds on multiple flight levels.
**Aircraft Operating Cost**

The direct operating cost for a cruising aircraft can be written as:

\[ J = \int_{t_i}^{t_f} [C_t + C_f(m,h,V)] dt, \tag{1} \]

where \( C_t \) and \( C_f \) are the cost coefficients of time and fuel. The fuel flow rate, \( f \), can be approximated by a function of aircraft mass, \( m \), altitude, \( h \), and airspeed, \( V \). Aggarwal [8] minimizes direct operating costs for long-range transport type aircraft in the absence of winds, and shows that the aircraft Mach number remains almost constant during cruise. This result is adopted here to simplify the search for the optimal solution.

For a constant airspeed \( V_p \), the cost function is rewritten as:

\[ J_i = \int_{t_i}^{t_f} [C_t + C_f(m,h,V_p)] dt. \tag{2} \]

The optimal \( V_i \) can be determined through an iterative process such that the arrival time constraint is met and operating cost is minimized. This operating cost depends on the total travel time and fuel flow rate during cruise. Total travel time is minimized by determining the optimal aircraft heading that yields the minimum-time trajectory in winds and the fuel flow rate is minimized by controlling cruise altitudes given \( m \) and \( V_i \). The computational effort is high, especially for long haul flights, when both winds and aircraft fuel burn are considered in the optimization since en-route meteorological conditions vary with location, and aircraft fuel burn depends on altitude.

In order to improve the computational efficiency of the approach, a two stage optimization strategy is proposed for narrowing down the search scope. The first stage optimizes an aircraft vertical profile along the track to determine the optimal cruise altitudes and en-route step climb times given the flight levels constraints. The second stage develops wind-optimal horizontal trajectory segments by determining optimal aircraft heading in winds based on the cruise altitudes and step climb times that are solved in the first stage.

**Optimal Vertical Profile**

This subsection develops an aircraft vertical profile based on the fuel consumption model in Eurocontrol’s Base of Aircraft Data Revision 3.6 (BADA) [9]. First, formulas for calculating the cruise altitude that has the minimum fuel burn rate are derived by assuming a constant cruise speed. Then, they are applied for optimizing the aircraft vertical profile along track based on the aircraft weight and true airspeed.

The fuel burn for aircraft during cruise, \( F \), is calculated as:

\[ F = t f, \tag{3} \]

where \( t \) is elapsed time. The fuel burn rate, \( \lambda \), for jets and turboprops is determined by the specific fuel consumption, \( SFC \), and thrust, \( Th \), and can be expressed in the following form:

\[ f = \frac{C_{fs} SFC \cdot Th}{1000}, \tag{4} \]

\[ SFC = C_{f1}(1 + \frac{V_{tas}}{C_{f2}}). \]

\( C_{f1}, C_{f2} \) are the thrust specific fuel consumption coefficients and \( V_{tas} \) is the true air speed. During cruise, thrust equals aerodynamic drag force, \( D \), that is a function of aerodynamic drag coefficients, \( C_D \), air density, \( \rho \), aircraft wing reference area, \( S \), and true air speed, and is expressed as:

\[ D = \frac{1}{2}(C_D \rho S V_{tas}^2). \tag{5} \]

The drag coefficient, under normal conditions and except during approach and landing, is specified as a function of the drag coefficient parameters, \( C_{D0}, C_{D2} \), and the lift coefficient, \( C_L \), where:

\[ C_D = C_{D0} + C_{D2} C_L^2, \]

\[ C_L = \frac{2mg}{\rho S V_{tas}^2}. \tag{6} \]

Note that the aerodynamic drag is a function of air density that depends on altitude.

The formulas for calculating the optimal cruise altitude that has the minimum fuel flow rate are
derived by taking the first order variation of the fuel flow rate with respect to the cruise altitude to zero. Under the International Standard Atmosphere (ISA) conditions, the tropopause is at 11,000 meters altitude; and the optimal aircraft cruise altitude, \( h_{\text{opt}} \), at or below the tropopause can be calculated by the following formula:

\[
h_{\text{opt}} = [1 - e^{-f(m, V_{\text{TAS}}) K_T R_{\text{g}} \rho_0 \text{ISA} \over 6.5}] \left( 1000 T_0 \text{ISA} \right)^{6.5}.
\] (7)

Above the tropopause, it is:

\[
h_{\text{opt}} = -f(m, V_{\text{TAS}}) R_{\text{gas}} T_{\text{trop}} \text{ISA}^{2} g \rho_{\text{trop}} \text{ISA}^{2} + 11000,
\] (8)

where \( f(m, V_{\text{TAS}}) = \ln \left( \frac{4 m^2 g^2 C_D^2}{S V_{\text{TAS}}^4 C_{D0}} \right) \), \( R_{\text{g}} \) is the real gas constant for air. The temperature gradient, \( K_T \), the sea level air density, \( \rho_0 \text{ISA} \), and the sea level temperature, \( T_0 \text{ISA} \), are all constant under ISA. The air density, \( \rho_{\text{trop}} \text{ISA} \), and temperature, \( T_{\text{trop}} \text{ISA} \), are also constants at the tropopause. The appendix shows the derivation of these formulas.

Optimal cruise altitudes are computed from Eqs. (7, 8) based on the atmospheric constants and aerodynamic drag coefficients that are aircraft type dependent. They also vary with aircraft mass and air speed. The thrust margin is also checked to ensure that it is positive when determining the optimal altitudes for each selection of mass and speed. The thrust margin is defined as the maximum cruise thrust minus the thrust required to maintain 100 ft/minute rate of climb at the selected air speed, at the optimal cruise altitude [10].

Figure 1 shows the optimal cruise altitudes for various combinations of mass and speed for the McDonnell-Douglas MD-11 aircraft. In general, optimal cruise altitudes are lower for higher weights and increase as air speed increases. Note that optimal cruise altitude decreases at very high air speeds when the thrust margins become negative. In these cases, optimal altitudes are recomputed and lowered to meet the thrust margin requirement.

During a flight, the optimal cruise altitude increases due to the continuous reduction in aircraft weight as fuel is used. An aircraft weight profile during cruise, for a constant airspeed, is generated using the initial aircraft weight at the start of cruise and the time history of the fuel burn rate. Figure 2 plots the vertical profile for optimal cruise altitudes in blue based on the weight profile in the absence of winds. Due to current air traffic regulation, however, aircraft are not permitted to follow this optimal climb profile, and can instead only cruise on certain flight levels depending on the direction of flights. This study adapts the standard in Reduced Vertical Separation Minima (RVSM) that eastbound aircraft fly odd thousands of feet while westbound aircraft fly even thousands of feet. The optimal legal cruise altitudes, \( h_{\text{opt}} \text{Legal} \), are determined given the set of flyable altitudes, \( h_{\text{Legal}} \), using the following equation:

\[
h_{\text{opt}} \text{Legal}(t) = \min_{h_{\text{opt}} \text{Legal}} \left( h_{\text{opt}}(t) - h_{\text{Legal}} \right).
\] (9)

The vertical profile for an eastbound flight is plotted in magenta in Figure 2. This vertical profile is generated without winds and assumes an instantaneous step climb. It is an approximation for the vertical aircraft profile for determining the en-route legal cruise altitudes and the total travel time at each altitude.
The second stage of the proposed optimization strategy optimizes aircraft horizontal trajectory segments in the presence of winds based on the vertical profile developed in the first stage. Minimizing total aircraft travel time also minimizes total fuel burn for a given vertical profile since the fuel burn rates are specified along the track. The minimum-time trajectory consists of the horizontal trajectory segments on the pre-determined legal cruising altitudes. They are optimized based on the cost-to-go associated with each extremal generated by forward or backward integrating the dynamical equations for optimal heading and aircraft motion from various points in the airspace. This subsection presents the dynamical equation for optimal aircraft heading and the horizontal trajectory optimization algorithm.

The aircraft equations of motion at a constant altitude above the spherical Earth’s surface are:

\[
\dot{\phi} = \frac{V \cos \psi + u(\phi, \theta, h)}{R \cos \theta}, \quad (10)
\]

\[
\dot{\theta} = \frac{V \sin \psi + v(\phi, \theta, h)}{R}, \quad (11)
\]

\[
\dot{m} = -f.
\]

subject to the conditions that thrust equals drag, flight path angle is zero, and the boundary constraints are met. \(\phi\) is longitude and \(\theta\) is latitude, \(\psi\) is heading angle, and \(R\) is the Earth’s radius. The east-component of the wind velocity is \(u(\phi, \theta, h)\), and the north-component of the wind velocity is \(v(\phi, \theta, h)\). It is assumed that the Earth is a sphere and \(R \gg h\).

The previous study [11] applies Pontryagin’s Minimum Principle to determine the heading angle that is assumed to be the control available for aircraft during cruise for minimizing the cost of travel time and climate impact. When neglecting the climate impact, the horizontal trajectory is optimized by determining the heading angle that minimizes travel time in the presence of winds. The dynamical equation for the optimal aircraft heading [11] is:

\[
\dot{\psi} = \frac{-F_{\text{wind}}(\psi, \phi, \theta, u, v)}{R \cos \theta}, \quad (13)
\]

where \(F_{\text{wind}}(\psi, \phi, \theta, u, v)\) is aircraft heading dynamics in response to winds and is expressed as:

\[
F_{\text{wind}}(\psi, \phi, \theta, u, v) = [-\sin \psi \cos \psi \frac{\partial u(\phi, \theta, h)}{\partial \phi} + \cos^2 \psi \sin \theta \frac{\partial u(\phi, \theta, h)}{\partial \theta} - \frac{\partial v(\phi, \theta, h)}{\partial \phi}]
+ \sin \psi \cos \psi \sin \theta \frac{\partial v(\phi, \theta, h)}{\partial \theta} + \cos \psi \sin \psi \frac{\partial u(\phi, \theta, h)}{\partial \phi} + \cos \psi \cos \psi \sin \theta \frac{\partial u(\phi, \theta, h)}{\partial \theta} - \frac{\partial v(\phi, \theta, h)}{\partial \phi}].
\]

A recent study [7] developed the same dynamical equation for computing minimum-time path. These studies [7, 11] reduced the trajectory optimization problem from a two-point boundary value problem to an initial value problem. Numerical algorithms such as collocation methods, used in [11], or interpolation techniques, as used in [7], can be applied to determine the optimal initial aircraft heading. In the case that an aircraft cruises at a single altitude, the minimum-time trajectory is completely specified by integrating Eqs.(1, 2, 14) simultaneously from the origin to the destination using the optimal initial aircraft heading.

In general, an aircraft cruises at multiple altitudes to accommodate weight reduction, thereby
minimizing fuel burn, as described in the previous subsection. The minimum-time trajectory is the combination of wind-optimal extremals on several different altitudes, each solved using wind conditions on that altitude. This study employs the concept of dynamic programming for constructing the minimum-time trajectory with wind-optimal extremals at different cruise altitudes. The optimal vertical profile provides the initial and subsequent optimal cruise altitudes as well as the transition times between the altitudes. The following five steps compute the horizontal minimum-time trajectory.

1. Using a range of different initial heading angles at the start of the initial cruise segment, a collection of wind-optimal extremals is generated by forward integrating Eqs. (10, 11, and 14) until the first step climb time. This step is illustrated by plotting the wind-optimal extremals in blue in Figure 3 for a flight from Anchorage to Hong Kong.

2. Using a range of different final heading angles at the destination, another collection of wind-optimal extremals is generated by backward integrating Eqs. (10, 11, and 14) at the second cruise altitude. This is done for a fixed period of time, estimated based on the difference between the total travel time and the first step climb time. The Magenta curves in Figure 3 shows these extremals at the second cruise altitude. These extremals provide the minimum time-to-go to the destination from any points along them. Delaunay triangulation and interpolation techniques can be applied to estimate the time-to-go from any point in the covered airspace region using the points on the extremals.

3. Identify the extremal from the collection generated in step 1 above that has the minimum time-to-go at the first step climb time (i.e. the end of the extremals). This step determines the wind-optimal trajectory segment at the first cruise altitude and the aircraft position at the first step climb time. The trajectory segment and the step climb position are shown by the blue dashed line and the blue cross in Figure 3. Note that the minimum time-to-go calculated based on the extremals in step 2 is only an approximation when the aircraft cruises at more than two altitudes.

4. After climbing to the new cruise altitude, repeat step 1 and step 2 at the new starting position and altitude. This is demonstrated in Figure 4, which plots the new starting position as a blue cross and the next step climb position as a magenta cross. The extremals and the minimum-time trajectory segment at the new altitude are plotted as solid and dashed magenta lines. This step is repeated until the last cruise altitude is reached.
When the last cruise altitude is reached, the minimum-time trajectory at the last altitude is calculated by forward integrating Eqs. (10, 11, and 14) using the correct heading angle at the start of the last cruise altitude. The heading angle is calculated by interpolating the aircraft headings from the backward extremals at the final cruise altitude.

The complete wind-optimal trajectory for a flight from Anchorage, AK to Hong Kong on August 1, 2010 is shown in Figure 5. The wind vectors at flight levels 360, 380 and 400 are plotted in blue, magenta and cyan, respectively. A flight level is a standard altitude of an aircraft in hundreds of feet. Each trajectory segment is optimized with respect to the winds at the associated flight level.

The wind magnitudes and directions are taken from the Global Forecast System (GFS). GFS is a global numerical weather prediction computer model run by the National Oceanic & Atmospheric Administration (NOAA) four times a day. It produces forecasts up to 16 days, and produces a forecast for every 3rd hour for the first 180 hours, and after that, every 12 hours. The horizontal resolution is roughly equivalent to 0.5×0.5 degree latitude/longitude. GFS data has 64 unequally-spaced vertical isobaric pressure levels ranging between 0.25-1000 mb, with enhanced resolution at low and high altitude.

**Experimental Setups**

The trajectory optimization algorithm is applied to assess the potential benefits of flying wind-optimal trajectories with an optimal vertical profile for commercial cargo flights operating at Anchorage, AK. The trajectory computations use air traffic and global wind data from October 2010, obtained from the GFS.
Ted Stevens Anchorage International Airport (ANC) is a major hub airport for cargo flights between the U.S. and Asia, being less than 9.5 hours from 90% of the industrialized world [12]. For this paper we analyze nearly 12,500 Federal Express (FedEx) and United Parcel Service (UPS) cargo flights from 2010. Based on these data, Figure 6 shows the 10 most popular origin airports for flights to ANC. Almost 80% of inbound FedEx and UPS flights depart from these 10 origin airports. Over 90% of outbound FedEx and UPS flights from ANC fly to the 10 destination airports shown in Figure 7. Table 1 lists the airport names and codes for the top origins and destinations. About 99% of the aircraft in the data set belong to the five aircraft types shown in Figure 8. These are the McDonnell-Douglas MD-11 (MD11), Boeing 767-300 (B763), Boeing 747-400 (B744), Boeing 777-200LR (B77L), and McDonnell-Douglas DC-10 (DC10).

**Figure 8. Top 5 Aircraft Types in 2010**

Aircraft trajectories are optimized based on the aerodynamic parameters and aircraft performance data provided by BADA for the five aircraft types described above. BADA does not include the B77L, so the aerodynamic parameters and aircraft performance data for the Boeing 777-200 (B772) are used instead. High takeoff mass is assumed for each aircraft type since commercial cargo flights are usually heavily loaded. Typical aircraft climb and descent profiles during initial climb, en-route step climbs and final descent are obtained for each aircraft type from BADA performance files for generating the complete aircraft trajectories. These are defined based on altitude, air speed and mass for each phase.
This study does not optimize cruise speed for each flight. The optimal speed depends on the cost performance index that is generally specified by the airlines and chosen according to their priorities. In addition, current BADA parameters, such as the drag coefficients, may only be valid at the specified nominal speeds. The current optimization procedure solves for the optimal speed by iterating a range of cruise speeds that requires a more detailed aerodynamic model. In this paper, the true air speed during cruise is calculated from the typical Mach number suggested by BADA.

Results

This section presents the potential benefits for commercial cargo flights of flying wind-optimal trajectories with an optimal vertical profile. Past studies focus on developing minimum-time trajectories in winds at a single altitude without considering potential fuel savings from en-route step climbs. The subsection on Comparing Wind Optimal Trajectories, below, compares wind optimal trajectories with an optimal vertical profile (WO) to wind optimal trajectories at a single flight level (WO1FL). The trajectories are compared for cargo flights between ANC and the top 10 origin and destination airports for flights to and from ANC. The subsection on Comparing Flight Plan and Wind Optimal Trajectories assesses the performance of the wind optimal trajectories with an optimal vertical profile (WO) and the flight plan trajectories (FP) along the same vertical profile.

Comparing Wind Optimal Trajectories

This subsection analyzes the WO and WO1FL trajectories for cargo flights to and from ANC. The performance of the WO trajectories is evaluated by assessing and comparing average fuel consumption and travel time of these trajectories to that of the WO1FL trajectories.

Figure 9 shows the average fuel savings in bar graphs for each origin, destination and aircraft type, for all cargo flights in 2010 to and from ANC. Flying the WO trajectories has a positive fuel saving for all of the origins and destinations except KOAK and KIND. Fuel savings are between 0.1% and 3% depending on the airport pairs. They are directly proportional to the length of the routes, which determines the number of en-route step climbs. The average travel time, fuel burn, and number of step climbs for the top 10 origins are shown in Table 2. The average time and fuel savings are shown in parentheses.
The potential fuel savings are very small for all domestic flights since most of them have only one step climb. Flights between ANC and KOAK or KIND have the shortest travel time. For these routes, performing an en-route step climb actually increases the total fuel burn. Note that the additional fuel burn required for each step climb is not considered when developing the aircraft vertical profile, which assumes instantaneous climb for simplicity in the optimization. Most international flights save more than 1% fuel depending on the aircraft types. The B744 and B772 have the largest amount of fuel savings while the MD11 and B763 have similar amount of fuel savings.

The WO trajectories for all the domestic flights have equal or longer travel times than the corresponding WO1FL trajectories. The additional time involved in climbing and descending is not negligible for these relatively short trips. The WO trajectories for all international flights except RJAA, which is the shortest of the international routes, have positive time savings. The time savings not only depend on the trip length but also on the flight direction. The travel time for each flight is affected by en-route wind magnitude and direction. Therefore, long-distance WO trajectories not only gain fuel savings from en-route step climbs but may also benefit from high-speed winds at higher altitudes.

### Flight Plan and Wind Optimal Trajectories

In the future, with improvements in air traffic management, route structures are likely to become more flexible. With these more flexible route structures, future air traffic will be able to choose to fly their preferred routes to a greater extent than is the case today. This subsection assesses the potential benefits for the FedEx and UPS cargo flights when they fly WO trajectories instead of FP routes. Both the WO and FP trajectories follow the optimal vertical profiles. Table 3 presents the average savings per flight, in descending order, for the top origins and destinations to and from ANC. The potential savings for the inbound flights to ANC are shown in the blue
cells and the data for the outbound flights from ANC are in the green cells. Figure 10 shows the average percentage savings for fuel in solid bar graphs for each origin, destination and aircraft type.

</table>

The average fuel savings are highly correlated to the time savings for each origin, destination and aircraft type. The savings for each flight are proportional to the total travel time difference between the WO and FP trajectories since both follow the same vertical profile. The magnitudes of time savings are affected by en-route wind conditions and the structure of the original flight plans.

Flying the WO trajectories has a positive saving in fuel and time for all the origins and destinations when compared to the FP trajectories. The domestic flights have up to 3% savings that are equivalent to about 5-10 minutes in time and 0.4-1.0 tonnes of fuel for the top three domestic airports: KSDF, KEWR and KMEM. The international flights can potentially save more than 10% by flying wind optimal trajectories. For the outbound flights to VHHH, RKSI and ZSPD, travel time is reduced by 23-54 minutes and fuel burn by 2.3-7.6 tonnes. In general, the savings are proportional to the trip lengths. They also depend on the direction of flight and aircraft types. Long-distance international flights gain large time and fuel savings for all aircraft types. Domestic flights with MD11, B744, or B772 have larger fuel savings than with B763 and DC10.
The domestic flights from ANC to KOAK and the international flights from RJAA to ANC have the smallest savings, respectively. Note that the accuracy of the assessed benefits is greatly affected by the quality of the flight plans in the database. FP trajectories that are simulated using flight plans with an incomplete list of waypoints lead to an underestimation of the required travel time and fuel burn. This is because flights are assumed to fly great circle routes between waypoints. If a flight plan has few waypoints, the FP trajectory is similar to the great circle trajectory for that flight. Subject to the wind conditions, great circle trajectories can be very similar to wind-optimal trajectories, especially for the short trips. Hence, the benefit of flying a wind optimal trajectory is underestimated for these flights.

Several other factors also affect the accuracy of the results. The actual vertical flight path of each FP trajectory is approximated by those of WO trajectory since the actual aircraft takeoff weight and airspeed profile for each flight are not available in the current database. Each simulated FP trajectory follows the vertical path that assumes a typical aircraft weight and an airspeed profile from BADA instead of the original vertical profile. This approximation may results in the performance underestimation for FP trajectories. In addition, the potential benefits for WO trajectories need to be discounted since they neglect the additional costs involved in operating inside foreign airspace.
Conclusions

This study developed a trajectory optimization algorithm that minimizes the cost of time and fuel burn by integrating a method for computing minimum-time routes in winds on multiple horizontal planes and an aircraft fuel burn model for generating fuel-optimal vertical profiles. It is applied to evaluate the potential benefits of flying wind-optimal routes in a seamless airspace for commercial cargo flights operating between Anchorage, Alaska and major airports in Asia and the contiguous United States. Flying wind optimal trajectories with fuel-optimal vertical profiles reduces average fuel burn of international flights flying at a single cruise altitude by 1-3%. Long-distance flights not only gain fuel savings from en-route step climbs but may also benefit from high-speed winds at higher altitudes. The potential fuel savings of performing en-route step climbs are very small for the domestic cargo flights since most of them have only one step climb. The optimal trajectories reduce fuel burn and travel time relative to their flight plan routes for all the airport pairs. Domestic flights can potentially save up to 3% on fuel burn and travel time, which is equivalent to about 5-10 minutes in time and 0.4-1.0 tonnes of fuel for the top three domestic airports. International flights can potentially save up to 10% on fuel and travel time by flying wind optimal trajectories, reducing travel time by 23-54 minutes and fuel burn by 2.3-7.6 tonnes. In general, the savings are proportional to the trip lengths, and depend on the en-route wind conditions and aircraft types.

Appendix

Taking the first derivative of the aircraft fuel flow rate with respect to the altitude to obtain the following equations,

\[
\frac{\delta F}{\delta h} = \frac{C_{f,1}}{1000} \left( D \cdot \frac{\delta SFC}{\delta h} + SFC \cdot \frac{\delta D}{\delta h} \right), \quad (A1)
\]

where

\[
\frac{\delta SFC}{\delta h} = \frac{C_{f,1}}{C_{f,2}} \frac{\delta V_{TAS}}{\delta h} \quad \text{and} \quad \frac{\delta D}{\delta h} = \frac{1}{2} \left( \frac{C_{D,2} \cdot S \cdot V_{TAS}^2}{\rho^2 \cdot S \cdot V_{TAS}^2} - \frac{C_{D,1} \cdot 4m^2 g^2}{\rho \cdot S \cdot V_{TAS}^2} \right) \frac{\delta D}{\delta h} \quad (A2)
\]

\( SFC \) is a constant when \( V_{TAS} \) remains unchanged for various cruise altitudes, i.e., \( \frac{\delta V_{TAS}}{\delta h} = 0 \rightarrow \frac{\delta SFC}{\delta h} = 0 \).

In general, \( \frac{\delta D}{\delta h} \neq 0 \); and solving the equation: \( \frac{\delta D}{\delta h} = 0 \)
yields \( C_{D,2} \cdot S \cdot V_{TAS}^2 = \frac{C_{D,1} \cdot 4m^2 g^2}{\rho \cdot S \cdot V_{TAS}^2} \). This implies

\[
\rho^2 = \frac{C_{D,2} \cdot 4m^2 g^2}{C_{D,0} \cdot S \cdot V_{TAS}^4}. \quad (A3)
\]

Below the tropopause (altitude \( h < 11000 \) m), the temperature is calculated as a function of altitude

\[
T_{ISA} = T_{\infty, ISA} - \frac{g}{k_r \cdot R_{\infty}} \cdot \ln \left( \frac{T_{ISA}}{T_{\infty, ISA}} \right). \quad (A4)
\]

and the air density is calculated as a function of temperature

\[
\rho_{ISA} = \rho_{\infty, ISA} \times \left( \frac{T_{ISA}}{T_{\infty, ISA}} \right)^{-\frac{R_{\infty}}{k_r \cdot R_{\infty}}} \cdot \left( \frac{g}{k_r \cdot R_{\infty}} \right)^{-1}. \quad (A5)
\]

Above the tropopause (\( h >= 11000 \) m), the temperature is a constant. The air density is

\[
\rho_{ISA} = \rho_{\infty, ISA} \times e^{-\frac{R_{\infty}}{k_r \cdot R_{\infty}} \cdot (h-11000)}. \quad (A6)
\]

The formulas for the optimal cruise altitudes under ISA are obtained using Equations (A3-A6)
